# INTERSIL

# IM6100 OPERATOR CONSOLE

## INTRODUCTION

The operator console for the IM6100 Prototyping System, 6900-CONTRL, consists of an array of console switches and indicators to facilitate computer operation and maintenance. The programmer, or operator, may start and stop program execution, examine and modify the contents of main memory, modify and display internal processor information, select various modes of microprocessor operation, manually load and execute short machine language programs or load and execute programs via the Teletype or high speed tape reader. Since the microprocessor register and internal control signals are not available externally, the modification and display of internal processor information must be done under program control.

In this note, we discuss the architectural features that are incorporated in the IM6100 design to facilitate control panel operation, as well as the specific implementation of an operator console.

## MICROPROCESSOR—PANEL COMMUNICATION

The panel must communicate with the microprocessor. Since the panel operation is inherently asynchronous in nature, the microprocessor must be "interrupted" to carry out the panel operations. However, there are certain drawbacks associated with the panel communicating with the CPU through the normal interrupt channel. The conventional interrupt system is inactive when the CPU is halted. Even when the CPU is running, the interrupt system is not always enabled. The console interrupt must be recognized by the CPU even if the CPU is in the halt state. The CPU must go into the run state to execute the panel routine and restore the original run/hlt state when exiting from the panel program.

An interrupt request is granted by the CPU executing a "hardwired" subroutine call of the interrupt service routine. This capability is built into the CPU state sequencer. Since the control panel routines are normally stored in read-only memory, the entry point of the subroutine must be guaranteed to be a "ROM location".

It is clear that the panel-CPU communication link must satisfy certain special requirements. These requirements can best be met by the provision of a dedicated panel interrupt request (CPREQ) line to the CPU which is treated differently from the conventional device interrupt request (INTREQ) line.

## "TRANSPARENT" PANEL MEMORY

The panel routines require memory. If part of the main memory is used for the panel software, obviously that portion of the memory cannot be used by the user. It is desirable to make provisions for a control panel memory which is distinct from the main memory. This is an important consideration since the final version of the user system most probably will not have a full fledged control panel and the system designer would like to use the entire capacity of the main memory for the specific system application. One could then design a stand-alone completely independent and portable panel with the routines residing in the panel memory. The panel program may share the same addressing space as the main program and the console operations will be "transparent" to the system user.

In the IM6100, a panel request is acknowledged if the CPREQ line is active low. The panel request is granted irrespective of the run/hlt state of the CPU. The CPU is temporarily put in the run state for the

duration of the panel routine and the CPU reverts back to its original state after executing the panel program. CPREQ also bypasses the interrupt enable system. An internal flip-flop (CNTRL FF) is set when the CPREQ is acknowledged which prevents further CPREQs from being granted.

As long as CNTRL FF is set, CPSEL, control panel memory select, becomes active low for memory references instead of MEMSEL, main memory select. CPSEL is used to distinguish between main memory and panel memory. The current contents of the program counter, PC, are deposited in location $0000_8$ of panel memory. The PC is then set to $7777_8$ and the CPU executes the panel program starting at location $7777_8$. The location $7777_8$ contains a jump instruction to the entry point of the panel routine. The panel memory system is expected to be organized with read-write memory in page 0 and read-only memory in the higher pages.

While the CPU is in the panel mode, MEMSEL becomes active during the final phase of "indirectly addressed" AND, TAD, ISZ, and DCA instructions. In indirectly addressed instructions, the address code refers to a memory location in which the 12-bit address of the operand is stored. The instructions are fetched from the panel memory. The indirect operand address pointer also comes from the panel memory. However, the final effective address refers to a location in the main memory. A main memory location may be examined by a TAD I instruction and modified by a DCA I instruction. Every location in the main memory is now accessible to the panel routine.

The CPU control structure is implemented by a microprogram stored in a programmable logic array (PLA). After the complete execution of an instruction, the sequencer scans power-on RESET, CPREQ, external RUN/HLT, Direct Memory Access Request (DMAREQ) and INTREQ, respectively. The request with the highest priority is granted. If there is no active request, the CPU fetches the next instruction in sequence. The CNTRL FF being set, masks off all requests except power-on RESET. The CNTRL FF also inhibits any program modification to the interrupt system. One of the interrupt system modifying instructions is then used to reset the CNTRL FF. When the CPU executes an ION, Interrupt On, instruction in the panel mode, it does not affect the interrupt system; instead, the CNTRL FF is reset after executing the next sequential instruction. One may exit from the panel routine by executing the following sequence: ION; JMP I $0000_8$. Location $0000_8$ of the panel memory contains either the original return address when the panel routine was entered or it may be a new "starting address" defined by the operator, for example, by activating the "LOAD PC switch". The CPU reverts to its original run/hlt state after executing the JMP I instruction, following an ION.

The control panel requests are usually triggered when the console function switches, LOAD PC, LOAD FLAGS, DEP MEM, EXAM, BIN BOOT, or USER FN, are activated. However, these function switches generate a CPREQ only if the CPU is in the halt state in 6900-CONTRL as shown in Figure 1. This is to prevent activation of these switches by accident while the user program is running. If the CPU information must be displayed in "real time", the CPREQ is generated by a timer at fixed intervals, for example, 30 times a second. The 6900-CONTRL timer requests are inhibited when the microprocessor has already granted an interrupt or DMA request. The

INTGNT, Device Interrupt Grant, and DMAGNT, DMA Grant, signals are used for this purpose. When a device interrupt is in progress, granting a control panel interrupt will interfere with the vectored interrupt priority scheme implemented in the Parallel Interface Element, PIE—IM6101. A control panel interrupt is not advisable when DMA operations are involved since it adversely affects the DMA response time as well as the DMA transfer rate.

## 6900-CONTRL

### SWITCH REGISTER

The switch register consists of 12 switches that enable the operator to load the program counter with a 12-bit address, to deposit a 12-bit data word in a selected memory location or to load the extended address bits if more than 4K of memory is used. The switch register can also be read by the user program with the OSR, OR the switch register, operate instruction.

## FUNCTION CONTROLS

### LOAD PC *Push Button*

The LOAD PC push button is used to load the Program Counter with a 12-bit address specified by the switch register. The PC information is displayed in the PC display. If the Rotary Switch is set to MD, then the DISPLAY will show the contents of the memory location immediately preceeding the location pointed to by the "new" PC.

### LOAD FLAGS *Push Button*

This push button is used to load switch register bits 6-11 into the Instruction Field, IF 0-2, and Data Field, DF 0-2, Registers if more than 4K of memory is used. If the display select rotary switch is set to FLAGS, the FLAG information is shown in the DISPLAY. If extended memory control is not used, the IF and DF information is not valid. Switch register bit 0 is loaded into the LINK.

### DEP MEM *Push Button*

If the operator wants to deposit data in a particular location of a specific memory field, the address must be loaded into the Program Counter by LOAD PC. Then the switch register switches must be set to correspond to the data to be deposited. The data is then deposited into the memory location specified by the content of the PC by activating DEP MEM. The PC is automatically incremented by one after the data is deposited to set up the next sequential memory address.

If the display select rotary switch was set to MD, the memory data, which was just deposited, is shown in the DISPLAY.

### EXAM *Push Button*

If the display select rotary switch is set to MD, the operator can cause the contents of the selected memory location to be brought from memory and displayed. In the memory examination mode, the Program Counter is incremented by one after the information is displayed to set up the next sequential memory address. Therefore, to modify the data in an examined location, the switch register and LOAD PC button must be used to return to the correct address.

If the Display Select rotary switch is set to AC, MQ or FLAGS, the DISPLAY will show the status of the Accumulator, MQ Register or extended address bits when the Exam button is activated. The PC is not affected.

### BIN BOOT *Push Button*

The BIN BOOT push button activates the bootstrap loader to read and store information contained in binary coded tapes, using ASR-33 Teletype paper tape reader or a high speed tape reader. For the bootstrap loader to function properly, the system must have a DEC PDP-8/E*compatible Teletype or high speed paper tape reader interface. The 6902-CPUTTY card provides for a DEC PDP-8/E*compatible ASR-33 Teletype Interface. Refer to Appendix I for a detailed description of the BIN BOOT operation.

### USER FN *Push Button*

This button may be activated to implement user defined routines. Refer to Appendix II for the PAL III listing of the control panel program. The panel memory is organized as 256 × 12 PROM and 16 × 12 RAM.

## MODE CONTROLS

### HLT *Switch* and CONT *Push Button*

The IM6100 can be stopped manually by flipping the HLT switch down. With the HLT switch up, the CONT push button is used to make the microprocessor execute programs starting at the location pointed to by the PC.

If the CONT push button is activated with the HLT switch down, the microprocessor will execute a single instruction pointed to by the PC and then halt. This single instruction capability is an extremely useful feature for debugging user programs.

### RESET *Push Button*

This button generates an initialize signal which is functionally equivalent to executing a CLEAR ALL FLAG, CAF $6007_8$, instruction. In the IM6100 prototyping system, they are wire-ANDed to generate the initialize signal.

The RESET and CAF will clear the AC, LINK, and all peripheral flags. The interrupt system is disabled. Refer to the application note entitled "Teletype Interface for the IM6100 CMOS Microprocessor" for the status of the Teletype flags on initialize.

The RESET differs from CAF in one important respect. The RESET will initialize all internal CPU flags, set the PC equal to $7777_8$ and then halt. Activating the RUN button will cause the CPU to execute the routine starting at location $7777_8$. RESET has the highest priority and pulsing the RESET while the CPU is executing a program in the panel memory will cause it to exit and go to the main memory location $7777_8$ and halt.

### FREE RUN *Switch* and SINGLE CLOCK *Push Button*

Since the IM6100 design is completely static, the CPU may be single clocked. If the FREE RUN switch is up, the microprocessor will run on the crystal oscillator on the 6902-CPUTTY card. The microprocessor can be single clocked by putting the FREE RUN switch down and then activating the SINGLE CLOCK. Two clock pulses are necessary for every state transition of the microprocessor since the microprocessor divides the input frequency by two for internal operation. Gating is provided on the CPUTTY board to ensure integral clocking and the SINGLE CLOCK is debounced to prevent false triggering in the single clock mode.

*Trademark of Digital Equipment Corporation. Maynard, MA.

### 30Hz *Switch*

If the 30Hz switch is up, the panel will generate CPREQ's at 30Hz. While the CPU is executing the user program, this feature may be used to display processor state information in "real time". However, one must be careful to include these "window" timings to the actual execution time of the user task to calculate the overall time if timing considerations are critical. One must, therefore, be cautious while using the DMA and INT features of the IM6100 since the "real time" display would adversely affect the worst case response time and throughput of the microprocessor.

This is a very convenient feature in the "single instruction mode" since the processor state information will be "immediately" available in the displays after executing the instruction. Also, while 30Hz is active, it is not necessary to press EXAM to look at new state information by changing the display select rotary switch. The 30Hz program overhead is less than one percent of the CPU active time.

### 3K ENABLE and 4K ENABLE *Switches*

The 4K EN switch, when it is down, disables writes into the 6901 M4KX12 CMOS memory plane. Since the state of the IM6100 is unknown as it is powered up, it is recommended that the memory is write protected when applying power to the system.

The 3K EN switch, when it is down, reconfigures the 4K × 12 memory into 1K × 12 RAM (locations 0000-1777$_8$) and 3K × 12 ROM (locations 2000-7777$_8$) to simulate a RAM-ROM system for user prototyping.

## DISPLAY

### Program Counter (PC)

The PC displays the contents of the Program Counter in the 30Hz mode. If the 30Hz option is inactive, the operator must press the EXAM push button with the ROT SW set to AC, MQ or FLAGS. If the ROT SW is set to MD, the PC will be updated by one to point to the next sequential address. When operating on memory while the machine is halted, the PC displays the memory address.

In the single clock mode, the PC displays the instruction address.

### Display

In the Free Run mode, the Display contains information which is selected by the Display Rotary Switch, AC, MQ, FLAGS or MD.

In the single clock mode, the Display follows the DX bus. Note that the Display information is valid only when DX contains valid information, i.e., the Display is undefined when the DX bus is tristated.

### RUN, XTA and IFETCH

These discrete LEDs show the active state of the RUN, XTA and IFETCH lines of the IM6100.

## CONCLUSION

The IM6100 is an excellent example of what can be provided in a microprocessor to facilitate panel functions. Undoubtedly, there are other ways of implementing these features. The IM6100 approach is interesting since it is extremely simple and straightforward. It requires only two additional pins and a minimum of internal logic, one additional line in the internal PLA. This approach does not require any new instructions and does not change the processor state. There are a number of panel options which can greatly increase the usefulness and flexibility of the microprocessor based system. For example, the panel can be used as a maintenance tool by storing test and exercise programs in the panel memory. Any additional feature is incorporated just by increasing the size of the panel memory to handle more software. The 6903-CONTRL may, therefore, be looked at as a completely independent, self-contained, standalone device which can be plugged into the system whenever panel functions are needed, and disconnected without disturbing any part of the user system.

# INTERSIL

# APPENDIX I

## INTRODUCTION

The BIN BOOT accepts tapes prepared with Digital Equipment Corporation PAL III, PAL D, PAL 8 or MACRO 8 assemblers and Intersil's FORTRAN/PAL III Cross Assembler. Diagnostic messages may be included on tapes. The BIN BOOT is functionally identical to the DEC BINARY LOADER described in the DEC Utility Routine Manual, DEC-81-RZPA-D, and the "Introduction to Programming" handbook. However, unlike the DEC BIN LOADER, the BIN BOOT does not use any locations in the main memory and hence all of main memory is available for user programs.

## EXTERNAL TAPE FORMAT

Tapes to be read by the BIN BOOT must be in binary-coded format and have about one foot of leader-trailer code (any code with channel 8 punched; preferably code 200). The first two characters represent the initial address or origin. The initial character of the origin has no punch in channel 8, while channel 7 is punched. The second character designating the origin has no punches in either channel 8 or 7. Data characters have no punches in channel 8 ro 7. A 12-bit binary word is represented by two 6-bit characters on the tape in channels 6 through 1, channel 6 of the initial character being the most significant bit. The data characters are loaded into sequential locations following the origin set up. If more than 4K of memory is used, the assembler outputs a "field-setting" command of the form 11 XXX 000 (channel 8-1) to indicate the memory field into which the following data is to be loaded. If for example, XXX were 101, all data following the field designator should be loaded into memory field five. Trailer tape is similar to the leader. A concluding 2-character group before the trailer represents the checksum and has no punches in channel 8 or 7.

## CHECKSUM

When any of the PDP-8 assemblers are used to produce a binary tape, a checksum is automatically punched at the end of the binary tape. This is the sum of all data on the tape including the origin but excluding diagnostic messages, leader/trailer code and field settings. The sum is accumulated character by character and not word by word. Carry out of the Accumulator, AC, is ignored.

If the checksum accumulated while using the BIN BOOT does not agree with the last two characters on tape (i.e., the checksum on the tape calculated and placed there by the assembler), an error in loading has occurred.

The microprocessor will halt after the tape has been loaded and the AC will be unequal to zero if a checksum error has occurred.

If the tape was started before the leader, the microprocessor will halt at the leader with AC equal to 7600 or 0000, depending on the number of blank characters read before the microprocessor halts.

## MEMORY EXTENSION USAGE

The BIN BOOT may be used to load the binary tape into any valid memory field. If the memory extension controller is not used, the extended memory field instructions of the BIN BOOT are treated as "don't cares".

## BIN BOOT PROGRAM

Refer to Appendix II for the PAL III listing of the BIN BOOT program.

The Program proceeds as follows: The incoming character is tested to see if it is a "rub-out" (all eight tape channels punched). If this is the case, all subsequent information coming from the reader is ignored until another rub-out is detected. This is the mechanism by which the assembler diagnostic messages are detected. They are preceded and followed by a single rub-out character. Within the diagnostic message any character is valid except, of course, a single rub-out character which would prematurely conclude the diagnostic message. Note that two consecutive rub outs within the diagnostic message would, in effect, be ignored.

Next the character is tested to see if it is leader or field setting. Leader information is ignored. The "change data field" routine is executed if the character is in the field format.

If the character is not part of the diagnostic message, leader or field setting, then it is part of the origin address, contains part of the data word and is part of the checksum and the appropriate course is followed. The BIN BOOT always "looks ahead" by one character to see if trailer follows the character just read. If it does, then the two characters read before the trailer is the checksum.
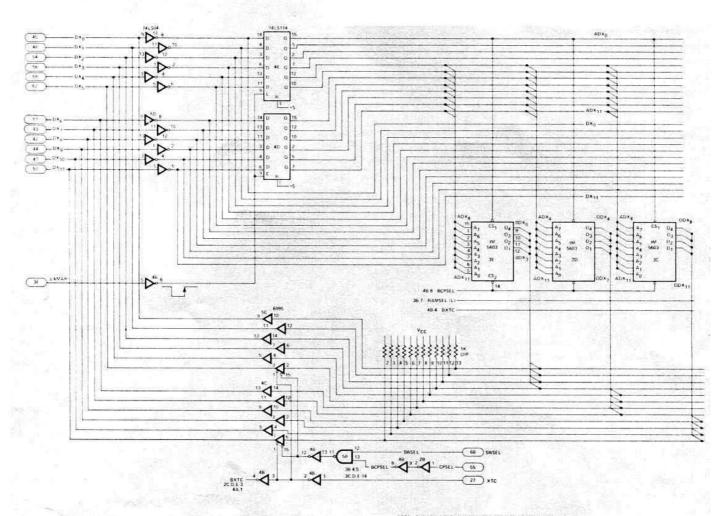

## BIN BOOT LOADING PROCEDURE

1. *Halt the machine.*
2. Place the tape to be loaded (tape must be in binary format) in the Teletype or High Speed reader. Make sure that the reader is "on line". The leader portion of the tape must be over the read head.
3. In the Data Field register, place the field into which the program is to be loaded with the LD FLAGS push button and the switch register.
4. When using the high speed reader switch register bit 0 must be 0. *When using the TTY reader, the switch register bit 0 must be 1.*
5. Press BIN BOOT.
6. The CPU halts after reading in the tape.
7. Examine Accumulator by pressing EXAM with the rotary switch set to AC. If the switch was set to AC while the tape was being read in, DISPLAY will automatically show the contents of AC. The AC must be equal to 0000, if the tape was properly read in. While the tape is being read, the PC shows the current origin and the Display shows the data being loaded into memory.

## STARTING THE PROGRAM

1. Press RESET to initialize the processor system, if required.
2. After the program has been successfully loaded, place starting address of the program in Switch register. Press LOAD PC.
3. Place the field where program exists in the Instruction Field register with the Switch register and LOAD FLAGS.
4. Bring the Halt switch to the run state (up).
5. Press CONTINUE.
